Sm$_2$Ti$_2$O$_7$ was loaded on the surface of HZSM-5 zeolite through a sol-gel route. HZSM-5 particles were coated with a thick layer of Sm$_2$Ti$_2$O$_7$ to form the composite. It was found that crystallization of pyrochlore phase Sm$_2$Ti$_2$O$_7$ begins at 800 °C. Continuous enlargement in Sm$_2$Ti$_2$O$_7$ crystallite size and cell volume are accompanied with the increase of calcination temperature. The bandgap energy of the samples calcined at temperature ranging from 600 to 1000 °C was found to be around 3.4 eV. BET specific surface area and pore volume of the materials continuously decreased with rising calcination temperature. The 70 % Sm$_2$Ti$_2$O$_7$/HZSM-5 calcined at 800 °C was found to have the greatest photocatalytic activity on RBR X-3B degradation.

Keywords: photocatalysis, Sm$_2$Ti$_2$O$_7$; calcination, sol-gel, HZSM-5.

1. INTRODUCTION

After nearly half a century of investigation, photocatalytic technology has become a potential advanced oxidation technique in dealing with environmental problems [1]. The focus is the synthesis of materials with strong activity on removing pollutants. The most widely studied photocatalyst is TiO$_2$-based material [2, 3]. Meanwhile, researchers are also interested in synthesizing titanates, e.g. SrTiO$_3$ [4], La$_2$Ti$_2$O$_7$ [5], Bi$_4$Ti$_3$O$_{12}$ [6] and CaTiO$_3$ [7]. La$_2$Ti$_2$O$_7$ was reported as a photocatalyst in environmental pollutants decompositions [8] and hydrogen evolution from water [9]. Pyrochboro structured Sm$_2$Ti$_2$O$_7$ has also been studied for their photocatalytic activity. Masayoshi Uno reported the visible light response by Sm$_2$Ti$_2$O$_7$ on photocatalytic generation of hydrogen [10]. Nashim prepared a composite Sm$_2$Ti$_2$O$_7$/SmCrO$_3$ for photocatalytic degradation of rhodamine dyes [11]. Akio Ishikawa introduced the doping of sulfur into Sm$_2$Ti$_2$O$_7$ to prepare Sm$_2$Ti$_2$S$_x$O$_{3-x}$ for the enhanced activity on water splitting [12]. Supporting is an effective method for improving photocatalytic activity of many kinds of materials. Zeolite is a kind of material possessing porous structure and large surface area. It is utilized as adsorbent and support for many purposes. Photocatalytic activities of TiO$_2$, La$_2$Ti$_2$O$_7$ and SrTiO$_3$ are greatly promoted after loading on HZSM-5 zeolite in our previous work [13, 14] and in the literatures [15, 16]. It is still interesting to support Sm$_2$Ti$_2$O$_7$ on HZSM-5 zeolite. In this work, Sm$_2$Ti$_2$O$_7$ was supported on the surface of HZSM-5 zeolite through a sol-gel route [13, 14]. The content of Sm$_2$Ti$_2$O$_7$ in the Sm$_2$Ti$_2$O$_7$/HZSM-5 is 70 % since it has the maximum activity. The effects of calcination temperature on the properties of the Sm$_2$Ti$_2$O$_7$/HZSM-5 were studied. Photocatalytic oxidation of Reactive Brilliant Red X-3B (RBR X-3B) was conducted to determine the activity of the composite.

2. MATERIALS AND METHODS

2.1. Synthesis of 70 % Sm$_2$Ti$_2$O$_7$/HZSM-5

Sol-gel method was used to synthesize samarium titanate. 1.1336 g samarium nitrate, 9 mL acetic acid and 10 mL deionized water were mixed together to form a solution. Another solution was composed of 8 mL ethanol and 0.86 mL tetrabutyl titanate. The two solutions were mixed to form a transparent precursor. The n(Sm)/n(Ti) molar ratio in the precursor was 1:1. HZSM-5 was added into the precursor subsequently. The mixture was stirred for about 1 h to form a sticky gel. The gel was dried at 110 °C for 15 h, and calcined for 3 h at the temperature indicated later. The obtained solid was ground and denoted as 70 % Sm$_2$Ti$_2$O$_7$/HZSM-5, in which the weight percentage of Sm$_2$Ti$_2$O$_7$ was 70 %.

2.2. Characterization methods

X-ray diffraction patterns were recorded by a D8Advance X-ray diffractometer. Monochromatized Cu Kα was chosen as the initial radiation source at λ = 1.5416 Å. A QUANTA 250 scanning electron microscope was used to observe the surface morphology. An integrating sphere was set up on a LAMBDAA 35 UV-Vis spectrometer to record UV-Vis diffuse reflectance spectra using BaSO$_4$ as a reference. An F-sorb 3400 analyzer was used to measure specific surface area and porosity.

2.3. Photocatalytic degradation of RBR-X3B

Photocatalytic activity of the 70 % Sm$_2$Ti$_2$O$_7$/HZSM-5 composite was studied by degradation of RBR X-3B. A 100 mL quartz beaker and a 20 W UV-light lamp irradiating at λ = 253.7 nm were set up as the lab-scale reactor. The initial concentration of RBR X-3B aqueous solution was 30 mg/L. 20 mg 70 % Sm$_2$Ti$_2$O$_7$/HZSM-5 and 50 mL RBR X-3B solution were stirred together for

E-mail address: wjzhang@aliyun.com (W. Zhang)
30 min in the dark to ensure adsorption-desorption equilibrium. Photocatalytic degradation of RBR X-3B started right after turning on the UV lamp. Absorbance of the RBR X-3B solution was measured at wavelength of 537.6 nm by a 721E spectrophotometer. Lambert-Beer law was used to calculate the concentration of RBR X-3B solution. UV-Vis absorption spectrum of RBR X-3B solution was recorded on a LAMBDA 35 UV-Vis spectrometer.

3. RESULTS AND DISCUSSION

XRD patterns of the 70 % Sm₂Ti₃O₇/HZSM-5 composites are shown in Fig. 1. Calcination temperature is a key factor for Sm₂Ti₃O₇ phase formation. The 70 % Sm₂Ti₃O₇/HZSM-5 samples calcined below 700 °C are in amorphous state. The weak diffraction peaks between 22–35° are attributed to HZSM-5 zeolite. Crystallization of pyrochlore phase Sm₂Ti₃O₇ begins at 800 °C. The diffraction peaks become sharper and stronger at higher calcination temperatures. The pyrochlore phase Sm₂Ti₃O₇ has a Fd3m lattice in cubic crystal system. The diffraction patterns of pyrochlore phase Sm₂Ti₃O₇ are in accordance to JCPDS No.73-1699. Phase transformation of Sm₂Ti₃O₇ and other impurities are not observed in the figure.

![XRD patterns of 70% Sm₂Ti₃O₇/HZSM-5 calcined at different temperatures](image)

Fig. 1. XRD patterns of 70% Sm₂Ti₃O₇/HZSM-5 calcined at different temperatures

Table 1 lists lattice parameters of pyrochlore phase Sm₂Ti₃O₇ in 70% Sm₂Ti₃O₇/HZSM-5 samples. A slight expansion of cell volume is accompanied with rising calcination temperature. Density of pyrochlore Sm₂Ti₃O₇ slightly decreases at the same time. Scherrer formula is used to calculate crystallite size of Sm₂Ti₃O₇ in the samples, based on the preferred (222) orientation [17]. The crystallite sizes are 27.6, 36.0 and 40.9 nm for the 70% Sm₂Ti₃O₇/HZSM-5 samples calcined at 800, 900 and 1000 °C. A continuous enlargement in Sm₂Ti₃O₇ crystallite size is accompanied with the increase of calcination temperature.

Fig. 2. SEM images of 70% Sm₂Ti₃O₇/HZSM-5 at different calcination temperatures; a – 600 °C; b – 700 °C; c – 800 °C; d – 900 °C; e – 1000 °C; f – HZSM-5

UV-Vis diffuse reflectance spectra of 70% Sm₂Ti₃O₇/HZSM-5 are given in Fig. 3 to show the effect of calcination temperature on bandgap energy. The bandgap energy of the sample is calculated using Kubelka-Munk theory [18] through the formula

\[(ahv) = A(hv-Eg)^n,\]  

where \(a, h, v, A\) and \(Eg\) are the absorption coefficient, Planck constant, light frequency, proportionality constant and bandgap energy, respectively [19]. The 70% Sm₂Ti₃O₇/HZSM-5 samples have strong absorption in the UV region while the absorption edge almost does not move.
when calcination temperature varies from 600 to 900 °C. The bandgap energy of the samples in this temperature range is around 3.42 eV. The bandgap energy of the samples calcined at 1000 °C slightly moves to 3.37 eV. These materials will not respond to visible light irradiation. The UV lamp used in this work can irradiate at 253.7 nm. The incoming photons have enough energy to initiate the generation of electrons and holes in all the Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub> samples.

![Absorbance](image)

**Fig. 3.** UV-Vis diffuse reflectance spectra of 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5 samples

Fig. 4 presents N<sub>2</sub> desorption isotherms of 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5. The samples prepared at temperature below 800 °C contain mesopores and macropores. The isotherms of the samples are classified as IUPAC type IV for mesoporous structured material. The abrupt enlargement in adsorption capacity at N<sub>2</sub> relative pressure over 0.9 is due to the interparticle macropores. The N<sub>2</sub> adsorption amount on these samples are much larger than the samples calcined at 900 °C and 1000 °C. Adsorption of N<sub>2</sub> molecules on the two latter materials is very weak in the whole N<sub>2</sub> relative pressure range.

![Pore size distribution](image)

**Fig. 4.** N<sub>2</sub> desorption isotherms of 70%Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5 calcined at different temperatures

Specific surface area and porous properties of 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5 are shown in Table 2. BET specific surface area of the materials continuously decreases with rising calcination temperature. Crystalline growth and particles aggregation during high temperature thermal treatment are the main reasons. The sample at 600 °C has the maximum specific surface area of 173 m<sup>2</sup>/g and the largest pore volume of 0.413 cm<sup>3</sup>/g. Organic substances in the gel were burnt out during calcination, leaving porous structure in the material.

The 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5 is composed of 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub> and 30 % HZSM-5. The specific surface of HZSM-5 is 223.8 m<sup>2</sup>/g. The average pore size and total pore volume in HZSM-5 zeolite powder are 1.91 nm and 0.1068 cm<sup>3</sup>/g, respectively. The HZSM-5 is quite thermal-stable that the above-mentioned data are almost unchanged after thermal treating. As a result, the variations in surface area and porous properties of 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5 are mainly attributed to the supported Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>, but not the HZSM-5 zeolite. On the other hand, since the HZSM-5 particles are coated with a thick layer of Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>, the micro pores in the zeolite can also be blocked by Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>.

The effects of calcination temperature on adsorption and photocatalytic degradation of RBR X-3B on 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5 are shown in Fig. 5. More than half of the dye can be removed after adsorption-desorption equilibrium on the samples prepared at temperature below 700 °C. This is due to the large specific surface area and pore volume in these samples. The adsorption capacity of the materials declines drastically with increasing calcination temperature as the result of shrinking surface area and porosity.

![Degradation](image)

**Fig. 5.** Effects of calcination temperature on adsorption and photocatalytic degradation of RBR X-3B on 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5. The irradiation time was 30 min

On the contrast, the samples calcined below 700 °C have poor activity on photocatalytic degradation of RBR X-3B. The active crystallite Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub> does not form at low temperature. The 70 % Sm<sub>2</sub>Ti<sub>2</sub>O<sub>7</sub>/HZSM-5 sample calcined at 800 °C has the maximum photocatalytic activity, while further increase of calcination temperature leads to a continuous declining of the activity. Crystallization and surface character are the two major
factors influencing the adsorption capacity and photocatalytic activity of the composite materials.

Fig. 6 gives the UV-Vis absorption spectra of RBR X-3B solution with extending illumination. The 70% Sm$_2$Ti$_2$O$_7$/HZSM-5 sample calcined at 800 °C was used as the photocatalyst. RBR X-3B solution has absorptions in both visible and UV regions. The red color of the solution comes from the conjugated chromophore in RBR X-3B molecule. The chromophore group has the maximum absorption intensity at 537.6 nm in the visible region. The removal of the dye from solution is recorded by measuring the absorption intensity at this wavelength.

RBR X-3B solution also has strong absorptions in the UV region centering at 230, 280, and 315 nm, corresponding to triazine ring, naphthalene ring and benzene ring. Intensities of all the absorption peaks constantly decline with prolonged illumination time. The broad peak between 450 and 570 nm almost disappears after 120 min of irradiation, indicating the degradation of the dye. The first order kinetic reaction constant is 0.01723 min$^{-1}$ on the 70% Sm$_2$Ti$_2$O$_7$/HZSM-5 sample calcined at 800 °C. At the same time, there are still apparent absorptions in the UV region. The triazine ring and naphthalene ring are hard to be decomposed.

![Fig. 6. UV-Vis absorption spectra of RBR X-3B solution during irradiation in presence of 70% Sm$_2$Ti$_2$O$_7$/HZSM-5 calcined at 800 °C](image)

4. CONCLUSIONS

The effects of calcination on the properties of the supported 70% Sm$_2$Ti$_2$O$_7$/HZSM-5 were studied. Pyrochlore phase Sm$_2$Ti$_2$O$_7$ begins to form over 800 °C. The cell volume slightly expands with rising calcination temperature. The 70% Sm$_2$Ti$_2$O$_7$/HZSM-5 samples have strong absorption in the UV region with bandgap energy around 3.4 eV. The surface area and pore volume of 70% Sm$_2$Ti$_2$O$_7$/HZSM-5 drop off with increasing calcination temperature. The adsorption capacity of the materials drastically declines at high calcination temperature. The 70% Sm$_2$Ti$_2$O$_7$/HZSM-5 sample calcined at 800 °C has the maximum photocatalytic activity.
