Vanadium dioxide (VO₂) is an interesting compound that exists in different polymorphic phases with varying characteristics and potential applications. In this study, fabrication and property analyses of three VO₂ polymorphs, namely VO₂ (B), VO₂ (A), and VO₂ (M), are described. Specifically, VO₂ (B) was prepared via hydrothermal method under a low synthesis temperature of 180 °C and a fast processing time of 24 h. In addition, VO₂ (A) and VO₂ (M) were derived from the as-synthesized VO₂ (B) using sequential hydrothermal treatment and calcination process, respectively. From the field-emission scanning electron microscope (FESEM) scans, belt-like VO₂ (B) nanoparticles with dimensions of as low as 35 × 130 nm² were formed. Further, hydrothermal treatment of the as-synthesized VO₂ (B) resulted to a flower-shaped VO₂ (A) due possibly to an oriented attachment mechanism. Meanwhile, annealing of the VO₂ (B) sample caused granular growth that produced plate-like and oblate shaped VO₂ (M) with dimensions of 135 to 306 nm in diameter and 28 to 37 nm in thickness. Moreover, the thermochromic properties of the samples were examined using differential scanning calorimetry (DSC) while the thermophysical properties of the samples were measured via microflash method. Accordingly, the prepared VO₂ (A) and VO₂ (M) samples exhibited phase transition behavior at 168.37 °C and 68.6 °C, respectively. Subsequently, changes in the thermophysical properties of each sample can be observed across the measured transition temperature. In particular, an increase in both the thermal diffusivity and thermal conductivity of VO₂ (M) can be observed when the temperature was raised from 50 °C to 100 °C. On the other hand, there is a noticeable decrease in the thermal conductivity of VO₂ (A) when the temperature was increased from 150 °C to 200 °C.

Keywords: hydrothermal synthesis, nanostructures, thermal conductivity, thermochromic, vanadium dioxide.

1. INTRODUCTION

Vanadium dioxide (VO₂) is a binary compound with unique physical and chemical properties [1]. Hence, it has caught the attention of material scientists and researchers for its functional and industrial applications. Interestingly, VO₂ exists in many polymorphic phases, such as VO₂ (B), VO₂ (A), VO₂ (M), VO₂ (R) and the relatively recent VO₂ (A) [2 – 4]. Of these polymorphs, VO₂ (M) and VO₂ (R) are considered to be thermodynamically stable and are known to exhibit thermochromic ability [5]. Accordingly, VO₂ (M) undergoes a reversible phase change to VO₂ (R) at a critical temperature of 68 °C [6]. At temperature below τc, VO₂ exists in a semiconducting state with a monoclinic crystalline structure; whereas, above τc, it becomes metallic with a rutile tetragonal structure [7]. More importantly, this phase transition results to changes in the material’s optical, magnetic, electrical and other functional properties [8–10]. For instance, the semiconducting VO₂ (M) is transparent to heat-carrying infrared (IR) radiation while the metallic VO₂ (R) is IR reflectant [11]. Hence, VO₂ (M) is widely considered for potential use in optical switching devices, thermal sensors, electrochromic and thermochromic devices, and as smart window materials.

Meanwhile, the metastable phase VO₂ (B) is being examined for its probable application as cathode material due to its layered structure [15]. Previous studies showed that the monoclinic-structured VO₂ (B) has good electrode properties and tunnel functions, which makes it have an excellent Li⁺ intercalation performance [16–18]. Furthermore, VO₂ (B) can undergo an irreversible phase transition to the thermodynamically stable VO₂ (R) when annealed at high temperature (450 °C or higher) under inert atmosphere or in vacuum [19]. Another VO₂ phase in metastable state is VO₂ (A). Compared with the other VO₂ polymorphs, its phase structure and some physical properties were reported more lately due mainly to the difficulty in its fabrication [20, 21]. It is considered as an intermediate phase between VO₂ (B) and VO₂ (R), and thus, is usually not observed during the synthesis process [22]. However, recent studies revealed that VO₂ (A) can be prepared in nanostructure form using hydrothermal process. In particular, VO₂ (A) can be produced via two-step hydrothermal synthesis using a system temperature of 270 °C [23] or a one-step hydrothermal treatment at a synthesis temperature of 250 °C [21]. In the aforementioned works, divanadium pentoxide (V₂O₅) was used as vanadium source while oxalic acid

nanostructured VO$_2$ polymorphs. VO$_2$ (B) nanobelts was polymorph.
sarcity of research relating to the properties of this first order and reversible, and its structural phase transition revealed that the phase transition from LTP-A to HTP-A is Popuri et al. on its crystal structure and phase transition Further, a follow-through reinvestigation was conducted by using 

Further, VO$_2$ (A) and VO$_2$ (M) were derived from the as - synthesized VO$_2$ (B)–H$_2$O system under a low temperature of 180 °C in 24 h. Compared with other works [21–24], the present study (B)–H$_2$O system. This was shown in the work of Zhang and colleague on its thermal properties, it was transferred into a 240 mL Teflon-lined autoclave. This means that the system had a fill ratio of 0.5. It is then heated at 180 °C for 24 h in an electric oven and cooled naturally. Afterwards, the precipitate was collected, washed with water and ethanol three times, and dried at 60 °C overnight.

2. Synthesis of VO$_2$ (A)

To begin the hydrothermal synthesis of VO$_2$ (A), 1.2 g of the as-prepared VO$_2$ (B) was dispersed in a beaker containing 120 mL deionized water under magnetic stirring. When the mixture attained good homogeneity, it was transferred into a 240 mL Teflon-lined autoclave. This means that the system had a fill ratio of 0.5. It is then heated at 180 °C for 24 h in an electric oven and cooled naturally. Afterwards, the precipitate was collected, washed with water and ethanol three times, and dried at 60 °C overnight.

2. Synthesis of VO$_2$ (M)

VO$_2$ (M) was derived from VO$_2$ (B) via annealing route. First, an amount of the as-prepared VO$_2$ (B) was heated in a tube furnace under nitrogen atmosphere at a temperature of 650 °C for 2 h. The heating rate was kept at 10 °C/min in the process. The tube was then cooled with the same heating rate to room temperature under nitrogen flow to prevent oxidation.

2.5. Characterization

The phase and crystalline structures of the prepared samples were analyzed using X-ray diffraction (XRD, X’pert Pro PANalytical Philips PW 3040) with a Cu-K$_\alpha$ radiation ($\lambda = 1.54060$ Å) generated at acceleration voltage of 40 kV and a current of 40 mA. Also, the data were collected at 2θ scanning range between 20° and 80° with a scanning step rate of 0.017° s$^{-1}$. Meanwhile, field emission scanning electron microscope (FESEM, JEOL-JSM7600F) was utilized to obtain high-magnification images of the synthesized powders for morphology analysis. Additionally, phase transition behaviors of the samples were investigated using differential scanning calorimetry (DSC, DSC822e, Mettler Toledo). In particular, the DSC was carried out at a temperature range between 20 °C and 200 °C with a heating rate of 10 °C/min under nitrogen flow. Further, optical properties were examined using a Fourier transform infrared spectrometer (FTIR, Thermo Nicolet 6700) using pelletized KBr. Finally, thermal diffusivity was measured using a light flash apparatus (LFA, Netzsch LFA457) at room temperature (25 °C) to 200 °C. This was done by molding and hydraulic pressing the obtained nanopowder sample into a pellet with a diameter of 10 mm and a thickness of 1 mm.
The sample’s diffractogram matches the VO₂(B) compound of space group C12/m1 with ICSD code 98-003-1439. In addition, after subsequent hydrothermal treatment of the as-prepared VO₂(B), the polymorphic phase VO₂(A) was successfully obtained as indicated in Fig. 1b. Correspondingly, all peaks can be indexed to VO₂(A) of space group P42/nmc with ICSD code 98-005-6196 (inset of Fig. 1b). Meanwhile, the VO₂(B) powder was converted to VO₂(M) after the annealing process. This can be inferred from the XRD pattern of the acquired sample as shown in Fig. 1c. The list of peaks (inset of Fig. 1c) clearly indicates that no other peaks was observed other than that of VO₂(M) of space group P121/c1 with ICSD code 98-007-8277. Indeed, it can be seen that all samples exhibited high, sharp and narrow intensity peaks, which denote that the samples are highly pure and well-crystalline.

After hydrothermal process involving the V₂O₅–H₂C₂O₄–H₂O solution, belt-shaped VO₂(B) was formed (Fig. 2a). The width and length of the belts were as low as 35 nm and 130 nm, respectively. Additionally, hydrothermal treatment of the as-prepared VO₂(B) resulted to VO₂(A) with flower-like shapes (Fig. 2b). The change in morphology may be due to an oriented attachment mechanism. Firstly, VO₂(B) nanobelts are broken down during the hydrothermal process. Subsequently, the nano-sized particles recombine to form nanobelts. Afterwards, these nanobelts would coalesce in a particular direction or orientation to form wider nanobelts or nanosheets due to the prolonged process. Lastly, layer by layer combination of the nanosheets formed the flower-like shape as illustrated in Fig. 2b. Interestingly, this result is not quite similar with earlier reports. In the work of Xu and colleague, nanorod VO₂(A) was synthesized via single-step hydrothermal process [22]. Likewise, Zhang fabricated VO₂(A) nanobelts using two-step hydrothermal method [24]. The differing results may be due to the change in synthetic conditions used in this current study. As elaborated in the works of Ji and colleague, synthetic conditions such as system temperature, duration, and fill ratio or system pressure can affect the growth of VO₂ polymorphs [25]. Meanwhile, after subsequent calcination process, the nanobelt VO₂(B) sample transformed into plate-like and oblate-shaped VO₂(M) particles as displayed in Fig. 2c. This granular growth was mainly due to grain growth mechanism. Correspondingly, there was disordering and breakage of the VO₂(B) nanobelts due to the dissociation of the V and O atoms. Further, the heat treatment caused reconfiguration of the V-O-based crystals which consequently results in the growth of VO₂(M) crystalline structure. With the prolonged annealing process, the nano-sized particles coalesce. Finally, agglomeration of the granules led to the formation of grains with oblate and plate-like shapes. Specifically, the dimensions of the synthesized VO₂(M) powder were 135 to 306 nm in diameter and 28 to 37 nm in thickness.
The phase transition characteristics of the synthesized VO₂ (A) and VO₂ (M) as measured using DSC are shown in Fig. 3. Accordingly, the VO₂ (M) sample displayed a prominent phase transition behavior at 68.60 °C which coincides with the phase transition temperature of bulk VO₂ (M).

![Fig. 3. DSC curves of the VO₂ (A) and VO₂ (M) samples](image)

The enthalpy (ΔH) of the sample was also determined by measuring the area of the curve in the DSC peak to examine the sample’s rate of transformation. Correspondingly, the calculated enthalpy of the synthesized VO₂ (M) is 53.77 J/g, which is greater than previous reports [26]. The sample’s excellent transition rate may have resulted from its high purity and good crystallinity as seen in its XRD scan in Fig. 1 c as well as its small grain sizes as illustrated in Fig. 2 c. Meanwhile, the VO₂ (A) sample exhibited shift in phase at 168.37°C as displayed by the faint peak in the inset of Fig. 3. Nonetheless, this value is very close to the reported value of the phase transition temperature of VO₂ (A). Also, the measured enthalpy of the sample is ΔH=2.55 J/g, which implies a very weak transformation rate. Indeed, this is consistent with the work of Oka et al., which inferred that the phase transition characteristic of VO₂ (A) is weak [27].

Furthermore, the FTIR spectra of the prepared VO₂ polymorphs are displayed in Fig. 4. The broad absorptions at 3420 cm⁻¹ and 1630 cm⁻¹ correspond with the stretching and bending vibrations of H₂O, respectively [28]. Also, the peaks at 2918 and 2852 cm⁻¹ can be linked with the asymmetrical and symmetrical vibrations of CH₃, respectively, while the 1384 cm⁻¹ band indicates the stretching vibration of C-O [29]. It can be noticed that the VO₂ (M) sample has lower peaks in these bands which implies reduction of impurities and H₂O molecules adsorbed on its surface. This is mainly due to the high temperature it was exposed to during the annealing process. In addition, all samples exhibited a double absorption band at 2360 and 2335 cm⁻¹ which are associated with the asymmetric vibrations of CO₂ [30]. Meanwhile, the rest of the peaks are characteristic bands of VO₂. Specifically, the absorption band at 1005 cm⁻¹ matches the characteristic stretching vibration of short V=O bonds [31]. Below this peak, the differing vibrational modes of the polymorphic phases of VO₂ can be discerned. The 528 cm⁻¹ band is attributed to the bending deformation of the V–O–V octahedral in VO₂ (B) [32]. Similarly, the peak at 514 cm⁻¹ can be linked to the delocalization of electrons in the V^4+–V^4+ bonds between VO₆ octahedra in VO₂ (A) [29]. On the other hand, the absorption band at 531 cm⁻¹ and 674 cm⁻¹ are ascribed respectively to the V–O–V octahedral bending mode and the first rutile packing of VO₆ octahedra in VO₂ (M) [28].

Moreover, the thermal diffusivity (α) of the samples as measured using a light flash apparatus is plotted in Fig. 5. Accordingly, from 25 °C to 200 °C, the heat transferring ability of the VO₂ (A) sample slightly decreased from α₂₅°C = 0.338 mm²/s to α₀₂₀₀°C = 0.294 mm²/s. Meanwhile, the thermal diffusivity of VO₂ (M) sample has an increasing pattern from room temperature (25 °C) to 200 °C.

![Fig. 4. FTIR spectra of the synthesized VO₂ (B), VO₂ (A) and VO₂ (M) samples](image)
Moreover, the thermal conductivity (κ) of the samples was calculated using the equation,

\[ \kappa = \rho \alpha C_p \]

where \( \rho \) is the material’s density, \( \alpha \) is the measured thermal diffusivity, and \( C_p \) is heat capacity. The measured densities of the pelletized VO₂ (A) and VO₂ (M) samples were 2.98 g/cm³ and 2.75 g/cm³, respectively. Inasmuch as these pellets were obtained by hydraulic pressing of nanopowder samples, their densities are lower than the theoretical values. The heat capacities, on the other hand, were determined from the DSC data in Fig. 3. Result of the measurements of \( \kappa \) is plotted in Fig. 6. It can be seen that the as-synthesized VO₂ (A) exhibits a slight increase in its \( \kappa \) from room temperature \((\kappa_{25^\circ C} = 1.020 \text{ W/m·K})\) to 150 °C \((\kappa_{150^\circ C} = 1.853 \text{ W/m·K})\); whereas, after its phase transition, its thermal conductivity decreases to \( \kappa_{200^\circ C} = 1.577 \text{ W/m·K} \) with \( \Delta \kappa = -0.276 \text{ W/m·K} \). Meanwhile, the profile of the plot of the thermal conductivity of the VO₂ (M) sample is consistent with the results reported by Oh and colleague [33]. Particularly, it is apparent that the thermal conductivity is increasing as the temperature is increased. The changes in thermal conductivity \((\Delta \kappa)\) from 25 °C to 50 °C, 50 °C to 100 °C, 100 °C to 150 °C, and 150 °C to 200 °C are 0.92, 1.58, 0.31, and 0.35 W/m·K, respectively. Hence, there is a great increase in \( \kappa \) across the phase transition temperature of VO₂ (M). Interestingly, this value \((\Delta \kappa = 1.58 \text{ W/m·K})\) is greater than the reported \( \Delta \kappa \) for VO₂ bulk and nanobeams [34].

4. CONCLUSIONS

The polymorphic phases of VO₂, namely, VO₂ (B), VO₂ (A), and VO₂ (M) were successfully prepared in nanostructure form. VO₂ (B) was prepared first by a facile hydrothermal synthesis of V₂O₅–H₂C₂O₄–H₂O system at 180 °C for 24 h. XRD and FESEM scans of the acquired dark-blue powder exhibited high purity and belt-like shape. Meanwhile, hydrothermal treatment of the as-prepared VO₂ (B) dispersed in H₂O at a low temperature of 180 °C for 24 h with a fill ratio of 0.5 resulted to the formation of VO₂ (A). FESEM image of the sample showed the formation of flower-like shape, while DSC scan displayed a weak phase transition at 168.37 °C. On the other hand, annealing the as-prepared VO₂ (B) at 650 °C for 2 h under nitrogen flow led to its transformation to the thermochromic VO₂ (M) polymorph with plate-like to oblate shape as observed in the FESEM scan. Furthermore, a discernible peak at 68.6 °C from the DSC curve coincides with the known phase transition temperature of VO₂ (M), which is at 68 °C. Meanwhile, the FTIR spectra of the samples showed their differences in the absorption bands particularly in the range between 1000 cm⁻¹ and 500 cm⁻¹. Additionally, the thermophysical properties of the VO₂ (A) and VO₂ (M) samples show noticeable changes across their phase transition temperature. Accordingly, a decrease in the thermal conductivity of VO₂ (A) sample can be observed after its phase transition temperature. As for the VO₂ (M) nanopowder, an increase in both its thermal diffusivity and thermal conductivity is evident across its phase transition temperature. For future studies, experiments can be carried out to investigate further the reasoning behind the changes in the thermophysical properties of VO₂ (A) and VO₂ (M) across their corresponding phase transition temperature.
